for prevent the ventricular reflux. The relation of flow rate and $T_{1/2}$ showed almost linear logarithmic graph. But the experimental $T_{1/2}$ was longer than calculated one in every flow rate. This reason may be incomplete mixing of the radionuclide in the reservoir instantaneously.

The degree of the discrepancy in these values was differed from the use of Rickham reservoir-Holter shunt to the flushing device Pudenz shunt because of different volume, mechanism and functional structure of the reservoir.

Our experimental graph is more useful and practical than the equation in clinically determination of the CSF flow rate through the shunt were measured with this experimental graph as 0.25 to 0.44 ml/min in sitting and more small in supine.

A Measurement of Cerebral Hemodynamic in Both Hemispheres with Radionuclide Angiography and Analog Simulation Method

Clinical investigators have continued to search for a simple method of measurement of cerebral blood flow that would achieve the widespread clinical usefulness of techniques such as brain scanning. This report deals with a simple method to determine hemodynamics of each hemisphere by means of analog computer simulation of radioencephalogram (REG).

Method: The basic principle of the analog simulation was based on the reports of Kuwahara et al.

A bolus of 10—15mCi $^{99m}$Tc pertechnetate in a volume of 1—5 mCi was injected into the femoral vein. Cranial activity was recorded in serial two frame per second by an Autofluoroscope. The radiocardiogram and input curve into the right atrium was also recorded for later analysis with analog simulation. The REG of both hemispheres were described by the selection of ROI on the brain image using a light pen of Autofluoroscope. Data distortion due to dead time (24 μsec) of the Autofluoroscope was corrected by the method of Jones et al.

With this method, CBF ratio between both hemispheres was calculated by the ratio of integrated value of input functions to both hemispheres. Mean transit time of the each hemisphere could be calculated as the sum of transportation lag and time constant of the brain.

Results: 1) Using the method described above, hemodynamics of both hemispheres was examined in healthy brains and some cases of cerebral infarction. CBF ratio between the both hemispheres was nearly one in the healthy brains and considerable decrease in the ratio was observed in stroke patients between hemispheres with cerebral infarction and intact hemispheres. 2) The study could easily be performed on a routine basis since only an intravenous injection was required. Combined with the study, radionuclide angiography and static brain scan could also be carried out. 3) Contamination of radioactivity in the external carotid arterial system was considerably smaller than Oldendorf's method and separation of the REG in both hemispheres was excellent in this method.
